Predicting Proliferative Retinopathy in a Brazilian Population of Preterm Infants With the Screening Algorithm WINROP

Anna-Lena Härd, MD, PhD; Chatarina Löfqvist, PhD; Joao Borges Fortes Filho, MD, PhD; Renato Soibelmann Procianoy, MD, PhD; Lois Smith, MD, PhD; Ann Hellström, MD, PhD

Objective: To retrospectively validate the WINROP (weight, insulinlike growth factor I, neonatal, retinopathy of prematurity [ROP]) algorithm in a Brazilian population. WINROP aims to predict ROP and is based on longitudinal weight measurements from birth until postmenstrual age 36 weeks. WINROP has predicted 100% of severe ROP in 3 neonatal intensive care unit settings in the United States and Sweden.

Methods: In children admitted to the neonatal intensive care unit at Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil, from April 2002 to October 2008, weight measurements had been recorded once a week for children screened for ROP, 366 of whom had a gestational age of 32 weeks or less. The participating children had a median gestational age of 30 weeks (range, 24-32 weeks) at birth and their median birth weight was 1215 g (range, 505-2000 g).

Results: For 192 of 366 children (53%), no alarm or low-risk alarm after postmenstrual age 32 weeks occurred. Of these, 190 of 192 did not develop proliferative disease. Two boys with severe sepsis who were treated for ROP received low-risk alarms at postmenstrual age 33 and 34 weeks, respectively. The remaining 174 children (47%) received high- or low-risk alarms before or at 32 weeks. Of these infants, 21 (12%) developed proliferative ROP.

Conclusions: In this Brazilian population, WINROP, with limited information on specific gestational age and date of weight measurement, detected early 90.5% of infants who developed stage 3 ROP and correctly predicted the majority who did not. Adjustments to the algorithm for specific neonatal intensive care unit populations may improve the results for specific preterm populations.

METHODS

Patients

The study group comprised all children admitted to Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil, during April 2002 through October 2008 who were screened for ROP, had weekly weight measurements, and survived.
from the initial ophthalmologic examination at 4 to 6 weeks of age to 45 weeks' PMA.

Hospital de Clínicas de Porto Alegre is a university-based tertiary hospital located in Porto Alegre, a city with a total population of approximately 3 million inhabitants in southern Brazil. All of the admitted patients were from an urban and cosmopolitan population in the region surrounding Porto Alegre, the main city in the state of Rio Grande do Sul. The Hospital de Clínicas de Porto Alegre neonatal intensive care unit cares for about 130 very low-birth-weight (<1500 g) preterm babies per year. At the time of the study, survival rates were 88.7% for babies with a birth weight (BW) of more than 1000 g and 1500 g or less and 47.8% for those with a BW of 1000 g or less,8 while some stage of ROP occurred in 24.7% with BW of 1500 g or less or less or GA of 32 weeks or less.9 The weight measurements were given to us as weekly weights, ie, we had no information on exact dates. An approximation was performed and we entered each weekly weight into WINROP as if it had been measured at exactly 1, 2, 3, and so on weeks after the infant's birth date.

The GA for each infant was determined by the neonatologists according to clinical criteria, early obstetric ultrasonography, and last menstrual date. The registered GA, in all of the patients, was approximated to the nearest GA week, for example, 27 weeks plus 3 days was recorded as GA 28 weeks; 27 weeks plus 3 days was recorded as GA 27 weeks.

**ROP SCREENING AND TREATMENT**

Ophthalmologic examinations consisted of binocular indirect ophthalmoscopy after pupillary dilatation with tropicamide, 0.5%, and phenylephrine, 2.5%, using a 28-diopter lens and a blepharostat. Scleral depression was used, when necessary, to better identify peripheral retinal alterations. Assessments were repeated periodically, according to the Brazilian guidelines for examining and treating ROP,10 which recommend screening for all babies born with a BW of 1500 g or less or GA of 32 weeks or less and for those babies with risk factors such as respiratory distress syndrome, sepsis, intraventricular hemorrhage, need for blood transfusions, and multiple gestation. The initial ophthalmologic examination should be performed between the fourth and sixth weeks of life and repeated weekly or more frequently according to the findings until full vascularization of the peripheral retina is observed or until 45 weeks' PMA. Retinopathy was classified according to the International Classification of Retinopathy of Prematurity (stage 1-5).11 The indications for treatment were changed during the study period when the results of the Early Treatment for Retinopathy of Prematurity study12 were published and will not be described in detail because the aim of the study was to study whether WINROP could predict proliferative ROP. However, no patient had ROP with zone 1 disease, and all laser-treated patients had stage 3 disease with plus disease. All ophthalmic examinations were performed by the same experienced pediatric ophthalmologist (J.B.F.F.).

**WINROP SCREENING**

The first step of the WINROP algorithm was developed using the methods of online statistical surveillance.13-15 Briefly, the algorithm using data from preterm infants with no ROP or with stage 1 ROP calculates the expected “safe” weight for each individual child. Then, the difference between expected weight gain and observed values of postnatal weight development at each point is calculated and accumulated. If the accumulated sum reaches a threshold limit, an alarm occurs.3

Data were retrospectively retrieved from the files regarding weight once every postnatal week until 35 to 36 postmenstrual weeks; these data, including GA at birth and BW, were entered into the surveillance algorithm by a person unaware of the maximum ROP stage. Weight had been measured according to clinical practice on a digital scale. One weight per week was recorded in WINROP. In the first step of the algorithm, an alarm statistic was calculated for each child to judge whether there was enough evidence to conclude that a significant slow down in growth had occurred. Figure 1 and Figure 2 show examples of actual weight gain in relation to expected weight gain in 1 infant with no alarm (Figure 1) and in 2 infants with high-risk alarms (Figure 2).

When the system gives an alarm for a growth slow down, the next step takes into account GA at birth and BW to test for indications that the child is at low or high risk for ROP. If the infant had a GA more than 29 weeks and/or BW more than 850 g, he or she was automatically classified as a low-risk infant. However, if both GA was less than 29 weeks and BW was less than 850 g, he or she was classified as a high-risk infant. For each child, weekly WINROP evaluations were at 1 of 3 levels: (1) no alarm, (2) alarm at low risk, and (3) alarm at high risk.3 In the case of an alarm (low or high risk), the PMA (week) was registered, as displayed by the system. After the WINROP analysis, the results were correlated with the maximum ROP stage for each child as extracted from the child’s files.

For the test characteristics, prior to the study we had hypothesized that all children with an alarm at high risk and/or an alarm at low risk before 32 weeks' PMA, ie, before the age when proliferative ROP is likely to occur, would need eye examinations while those with no or low-risk alarm (more than 32 + 0 weeks’ PMA) would not.

**STATISTICAL ANALYSIS AND ETHICS**

The surveillance system using the variables weight gain, GA, and BW was evaluated regarding sensitivity (probability that an alarm occurs, given that the child develops stage 3 ROP) and specificity (probability that an alarm does not occur, given that the child will not develop stage 3 ROP). The negative and positive predictive values were calculated using the sensitivity, specificity, and prevalence in the present study group. We calculated 95% confidence intervals for estimated binary proportions (sensitivity and specificity) using the exact method from Clopper-Pearson.16 The study protocol regarding postnatal weight gain and ROP was approved by the Research Ethics Committee of Hospital de Clínicas de Porto Alegre (No. 03-248). The protocol also conforms to the provisions of the Declaration of Helsinki in 1995 (as revised in Edinburgh, Scotland, 2000).
In this retrospective study of a Brazilian population of preterm infants, WINROP correctly identified 19 of 21 children (90.5%) who had developed proliferative ROP. In previous studies from Sweden and North America, 100% of subjects developing stage 3 ROP were identified. There may be several reasons for this discrepancy. WINROP is based on data from infants with no or stage 1 ROP at a single neonatal intensive care unit in Sweden. In the Swedish study of the use of weight only in the WINROP algorithm, no child with a GA of 28 weeks or more developed stage 3 ROP, in contrast to the Brazilian population where 10 of 21 infants who developed proliferative ROP had a GA of 28 to 32 weeks. It is well known that more mature infants get ROP in developing countries and that screening criteria have to be modified accordingly.17 One of the “missed” infants had an ap-
approximated GA of 32 weeks at birth and an alarm at week 33 PMA. In this case, an alarm before or at 32 weeks was not possible. So theoretically, because alarm levels have been set for the Swedish population, having no infant with proliferative ROP after a GA of 29 weeks, the method could not have been more sensitive. In the Swedish and North American studies, GA as well as dates of weight measurements were determined and registered more exactly using full gestational weeks plus days, while in this study, approximation to full weeks was performed. This might have influenced the results in the second “missed” infant with a GA of 28 weeks where an alarm was given at 34 weeks’ PMA. If this infant’s GA was 29 weeks, an alarm was given at 32 weeks and he would thus have been correctly identified.

Despite that WINROP appeared to be somewhat less efficient in this Brazilian population than in populations from Sweden and the United States, it correctly identified 90.5% of infants who had developed proliferative ROP and 55% of those with no or only mild ROP.

The purpose of ROP screening at present is to identify infants who need treatment with laser or cryotherapy to prevent blindness. Of those infants currently subjected to repeated eye examinations, less than 10% will need any treatment; in the rest, the disease will never develop or will regress spontaneously.

WINROP provides a tool to identify infants at risk for sight-threatening ROP. Although it has to be modulated to function optimally in countries where more mature infants develop ROP, it is in this context that it can be most useful since it is entirely based on weight measurements that are already performed as part of clinical practice all over the world. We believe that additional neonatal intensive care unit data from developing countries will help in modifying the algorithm for these populations. Until then, information from this population helps determine how weight measurements and GA estimation can be standardized to make the algorithm more universally applicable. As previously suggested, the close association between poor neonatal weight development and ROP indicates that optimizing growth may be one way to reduce ROP.
